March 2020

Declaration of Authorship

I, Douglas Dziedzorm Agbeve, declare that this thesis titled, ‘SIMULATION OF A NOVEL MAC PROTOCOL WITH NS3’ and the work presented in it are my own. I confirm that:

- This work was done wholly or mainly while in candidature for a research degree at this University.
- Where any part of this thesis has previously been submitted for a degree or any other qualification at this University or any other institution, this has been clearly stated.
- Where I have consulted the published work of others, this is always clearly attributed.
- Where I have quoted from the work of others, the source is always given. With the exception of such quotations, this thesis is entirely my own work.
- I have acknowledged all main sources of help.
- Where the thesis is based on work done by myself jointly with others, I have made clear exactly what was done by others and what I have contributed myself.

Chapter 1

Introduction

The later part of the past decade has seen a tremendous increase in the research of Internet of Things (IoT) devices mostly geared towards energy efficiency. This is in part, due to the fact that IoT devices have an underlining positive factor of having to save energy usage and hence must be design as not excessively use energy in itself. Not only do these interconnected devices provide comfort but have also become critical parts of our daily lives: saving lives, expediting interactions and transactions. Another factor that fueled the advancement in the research of energy efficient IoT devices is the enormous progress made in the field of Machine learning specifically Reinforcement learning.

Maximizing a numerical reward signal by learning which actions to take in a given situation is what Reinforcement learning is about. The actions to take by the learning agent pertaining to various situations are not preprogrammed into the learner, but instead this is discovered by taking the actions that maximize the reward margin[1]. This works in the cycle of sense-action-goals and learning is from immediate interactions with the environment.

The APT-MAC protocol, which is the focus of this paper, seeks to solve the problem of the reliance on battery. The protocol utilizes the Multi-Arm Bandit algorithm, a reinforcement learning algorithm, in tandem with Radio-frequency identification (RFID) signals to enable battery-free communication of wireless devices[2].

The aim of this work is to simulate the APT-MAC protocol in NS3 and to show why it was the best option compared to static TDMA protocol.

1.1 The Protocols

Even though the quality of a network service is a cooperative effort of all the stack of communication protocols, the MAC layer is of a peculiar importance as it handles the sharing of the medium on which all other upper-layered protocols depend. MAC protocols do not only solve the problem of medium sharing, hence, support for reliable communication but also, in Wireless Sensor Networks, control of energy utilization, achieve through duty cycling and retransmissions or transmission power control[3].

In wireless sensor network, the MAC protocols are broadly classified into contention-based MAC protocols and scheduled-based MAC protocols depending on how the medium is accessed[4].

The medium in a contention-base MAC protocol is accessed by all the nodes and, as the name suggests, the nodes contend for access to the medium this may result in collision hence, to prevent collision access to the medium is negotiated through probabilistic coordination. A sending node listens to shared medium before sending, if the medium is busy, sending is halted for a specified period of time before retrying. Examples of contention-based MAC protocols used in wireless sensor network are ALOHA (Additive Link On-line Hawaii System) and CSMA (Carrier Sense Multiple Access)[5].

Nodes' medium access in a schedule-based MAC protocol is split into either frequency, Frequency Division Multiple Access, or time, that is, Time Division Multiple Access, or orthogonal pseudo - noise codes (Code Division Multiple Access). Collision is prevented in the medium by making different nodes access the medium in their designated time or frequency and hence not interfering with each other.

This section deals with the description of the protocol: APT-MAC and Time Division Multiple Access (TDMA).

1.1.1 TDMA

In TDMA, the total duration of communication is divided into fixed number of time slots. Time slots are configured into time-frames that are repeated periodically. Each node is allocated a time slot in a time-frame and is allowed to only transmit in that time slot. The TDMA frame structure has extra overhead; preamble and trail bits, added to the information message or bits. Time slots are what make up the information bits/message. Figure 1.1 shows the details of the frame structure.

Preamble: contains the address and synchronization information of the base (sink) node and the identification information of the other nodes.

Guard time: necessary to prevent time-drifting over time.

Trail bit: for error detection in the form of checksum or cyclic redundancy check.

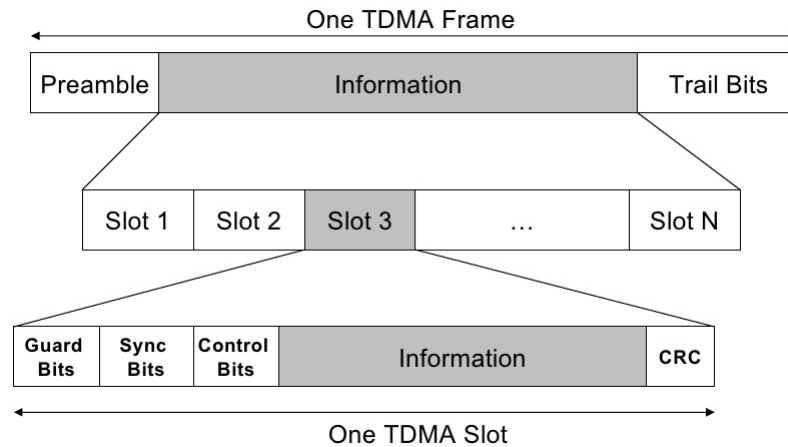

FIGURE 1.1: Frame Structure

The inadequacies of TDMA, chief among them with respect to the aim of the referenced paper [2], is static slot assignment. The slots are assigned before transmission and does not change whatsoever during the transmission process, this does not serve the purpose of a protocol that is needed to scale according to the transmission requirements of the nodes.

1.1.2 APT-MAC

APT-MAC protocol is a zero configuration - manual configuration not needed - mac protocol. Reinforcement learning is utilized to learn the required rate of transmission of each active node and continually update the transmission requirements

of nodes. An overview of the reinforcement learning algorithm is given, followed by how it is used the APT-MAC protocol.

1.1.2.1 Multi-Arm Bandit

When one is made to choose between multiple actions with an unknown reward for each action taken and the goal being to maximize the profit margin through a series of actions, the problem is classified as the multi-arm bandit problem. For example, a website deciding on which adverts to show to its visitors. The proprietor must maximize advertisement revenue but does not have enough information about the visitor to pursue a specific strategy, however, there are a large pool of adverts to choose from. This begs the question of which adverts will drive the maximum revenue. The websites, hence, needs to make a series of decisions, each with unknown results and rewards.

When a set of action(s) is found to maximize reward and those are actions are selected over and over again it is termed *Exploitation*, thus the knowledge of the actions is being exploited whereas when an action is selected for which the reward is not known is *Exploration*. An optimum balance between the exploitation and exploration is needed in most cases to achieve maximum reward.

From a more scientific standpoint, Bernoulli multi-armed bandit can be described as an *action reward-function* tuple $\langle A, R \rangle$. At each time step t an action $A = a$ is taken and a reward $R = r$ is received with reward probability $\{\theta_1 \dots \theta_K\}$. The expected reward which is the value of the action taken is given by $Q(a_t) = \mathbb{E}[R|A = a] = \theta$. The goal is to maximize $\sum_{t=1}^T r_t$, the cummulutative reward, hence an optimal action a^* with and optimal probability θ^* thus:

$$\theta^* = Q(a^*) = \max_{a \in A} Q(a) \quad (1.1)$$

Broadly, the various algorithmic solutions to multi-arm bandit problem can be categorized as; no exploration - greedy, random exploration and exploration intelligently with reference to probability [1].

1.1.2.2 APT-MAC protocol overview

The "battery-freeness" of the protocol is as a result of the use of sensor-augmented RFID tags.

During initialization, the reader sends discovery queries to all nodes and each is assigned a unique identification. In querying tags in such a way as to minimize the difference between the sensor's data generation time and the time of delivery of data to the reader, the Multi-Arm Bandit, describe above, is used. The reader, agent in this case, queries each node - set of actions - and can be in one of two states: querying or ready to query. Expected reward is calculated with the formula 1.2 with the expected reward of each action stored in vector Q .

$$Q(a_i)(n+1) = Q(a_i)(n) + \alpha(Reward - Q(a_i)(n)) \quad (1.2)$$

n is the time slot of the query, a_i is the action of querying tag i and α is the learning rate.

A more detailed explanation of the protocol, such as the learning rate parameter and the evaluation of the *Reward* can be found in [2].

Chapter 2

Simulation

The activities of the simulation is described in this chapter. An overview of NS-3 is given, which is then followed by the actions taken, setup used, assumptions made and overall explanation of the simulation.

2.1 NS-3

A discrete event network simulator, NS-3 is used extensively in network research and education. The workings and performance of packet data network are modelled and NS-3 provides a platform for the simulation and experimentation of various packet-based research. C++ and Python are the predominant language in which NS-3 is written with *waf* as the build system. Design of NS-3 capitalizes on the object oriented nature of these languages[6].

There are various components of packet-based network, fundamentally there are the endpoint devices, routers, NIC devices, switches and the medium of exchange. These components, however in NS-3, are abstracted to reflect what the components actually do. The endpoint devices are called *Nodes*, exchange medium - *Channel* and the applications that are generating the packets are *Applications* just to name a few. The file/folder structure of a simulation consist of a model which depicts the fine details of the simulation, a helper that is supposed to include files containing the installation helper functions, an example folder to implement an example of the simulation. There are also doc and tests folders and the just as their names suggest they hold documentation and tests files.

Installation of the NS-3 is not needed to get a simulation running, as the examples or experiments can be run using the binary files gotten from the build process. It is actually not recommended to do installation of NS-3. Installation in this case refers to running the command `./waf install`.

2.2 Setup

The simulation was performed on a Gentoo Linux flavor computer with a 64 bit Intel Eight-Core processor with model name *Intel(R) Core(TM) i7-8565U CPU @ 1.80GHz* and RAM of 32GB. Version 3-30 of NS-3 provided the platform on which to undertake the research. At the time of setting up, this version was the latest most stable release.

NS-3 is a voluminous software, the faster processor is needed, as a change to any file would mean rebuilding the file and its dependencies and those that depend on it. The version is also critical. Most versions are not backward compatible hence what works on 3.29 might not work on 3.30 without a little tinkering.

Gentoo Linux, even though time consuming and quite advance in installation and setting up, turns to be one of the fastest linux operating systems available. This is partly due to the fact that source codes are compiled on the host computer with specific flags set for optimality.

2.3 Components

For a data packet to move from one endpoint to another, there are components such as, the packet generating and receiving nodes which will have NIC, the medium(s) through which the packet traverses also forms a part of the components.

There are three critical parts, worth mentioning for this simulation; the header which is attached to the packet, tag-augmented sensor devices and the reader, which, in this case, is augmented with a server.

A discussion of the various components follow next.

2.3.1 Packet Header

Various parts of a packet header which is added to a payload enable the packet to get to its intended destination. A 4-byte(32 bits) header was created, having two fields of 16 bits each representing the packet type being sent: data packet or broadcast and the state of the tag augmented sensor: whether a new data is available for transmission or not.

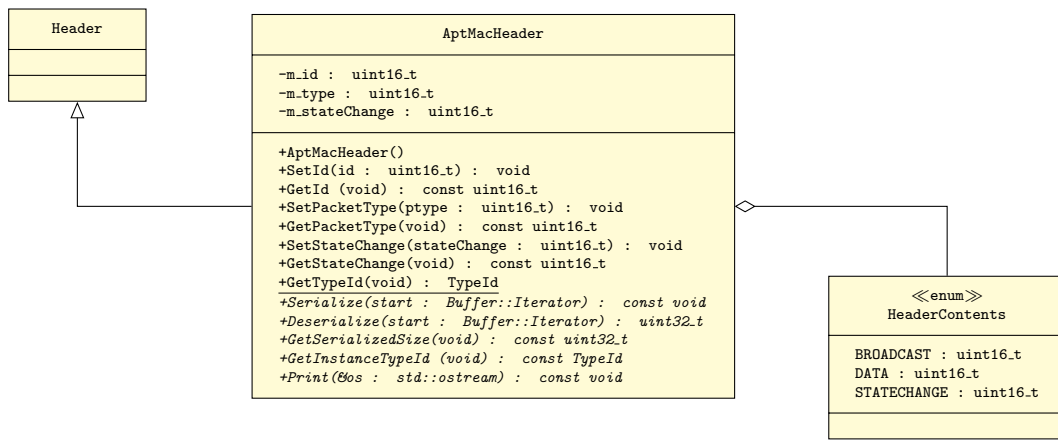

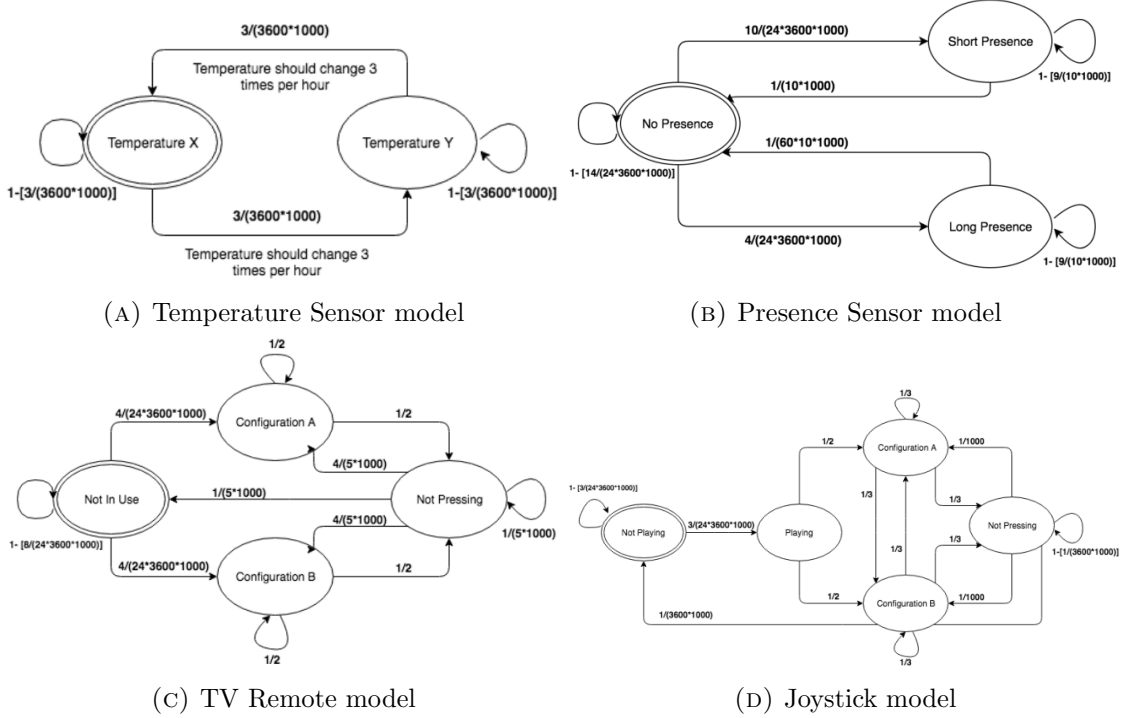

FIGURE 2.1: Class Diagram - APT-MAC Header

The UML class diagram is illustrated in Figure 2.1. The *constructor*, *getter* and *setter* functions are for their usual purposes. *Serialize* function puts the various fields of the header in series by writing them from host-order to network-order and the *Deserialize* reads from network-order to host-order. *Enum HeaderContents* holds the value of the various fields of the header.

2.3.2 Tag Augmented Sensor Devices

Devices in a smart home are broadly classified under three categories: periodic (e.g., temperature sensors), real-time (e.g., joystick, cameras) and event based (e.g., presence detector, remote of appliances)[2]. The state changes of the various devices were modelled according to Markov Chains[7].

Figures 2.2a to 2.2d, taken from [2], depicts the transition probabilities of the various states a device could be in. The state change is based on time. Taking fig 2.2a for instance, it was found that a temperature sensor produces new data three times in an hour hence the various probabilities with respect to time in milliseconds. There are two states in with a temperature sensor and with a probability of $3/(3600 \cdot 1000)$ it changes from, lets say, state X to Y or vice versa and with $1 - 3/(3600 \cdot 1000)$ stays in its state.

Markov Chain with a transition probability, say T , and an initial state probability vector distribution q . The probability of the chain being in state S_i after n steps is the i^{th} entry in the vector given by

$$q^n = q * (T)^n \quad (2.1)$$

To simulate the state change based on equation 2.1 and also, taking into account the discrete time with which the changes occur. The next state vector probability was computed with the n^{th} step being the current time stamp of the simulation.

For each tag-augmented sensor node, when a packet is received, the header is checked to determine the type of packet. If the packet is that of broadcast, a broadcast reply is automatically sent to the reader with a payload of the current

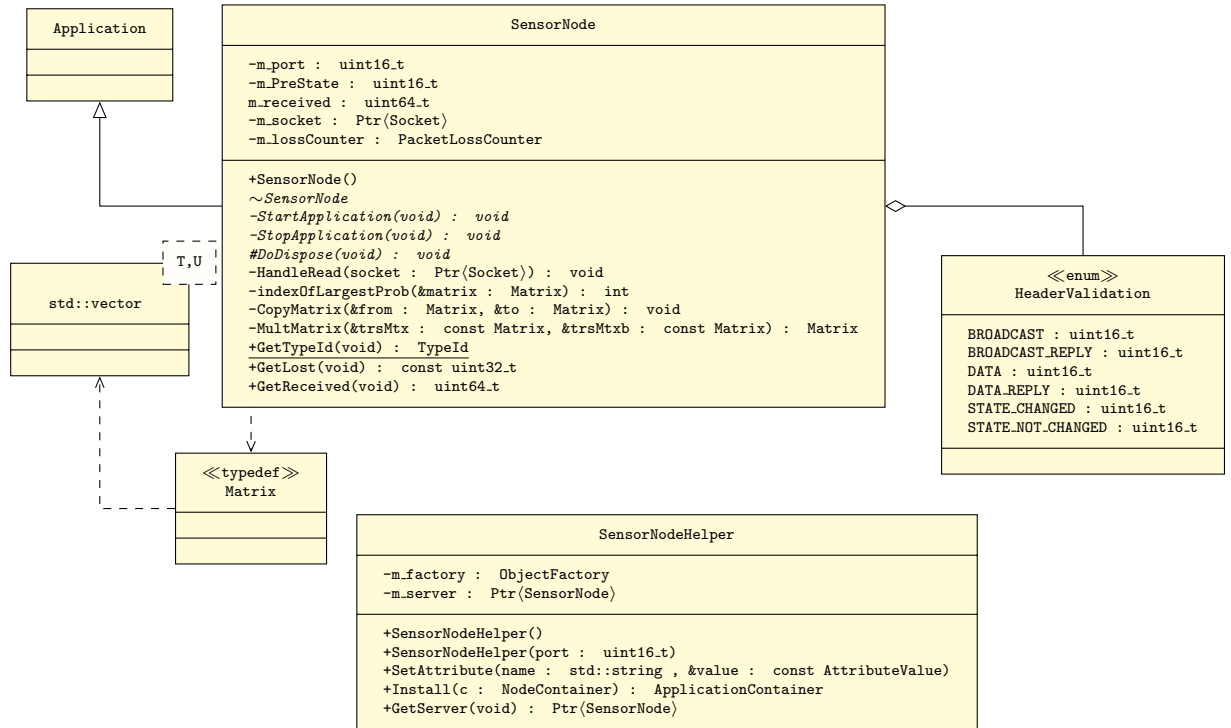

FIGURE 2.3: Class Diagram - Sensor Nodes

data. A data request packet requires the sensor node to reply with data. A current state vector probability is calculated and the index with the maximum value is the state of the sensor node. If the computed current state is the same as the previous state, a *state-not-changed* flag is set in the packet header, data reply flag is also set and packet sent to the reader.

The difference in the various sensors is their transition matrix and the initial state vector, as shown in 2.2a - 2.2d, hence the one class for all the sensor nodes.

Class diagrams of the *SensorNode* class and its *helper* class are shown in figure 2.3. A brief explanation regarding the tasks of the essential functions of the classes follows.

StartApplication: the first function run to start the application. It sets up a socket, binds it to a local address and configures the function to handle a received packet.

StopApplication: stops the application by resetting the packet-received call back function and closing the socket.

HandleRead: this is the packet-received call back function. It is invoked when a new packet arrives in the socket or when there is data/packet to be read in the socket file. The type of packet received is determined by examining the header. A broadcast-reply is sent back to the reader if a broadcast packet is received by setting the broadcast-reply flag in the header. For a data-request packet, the current state of the sensor node is retrieved from the *NextState* function and compared with the previous state. If the states (previous and current) are equal, data-reply and state-not-changed flags are set in the packet header and if the states differ, state-changed and data-reply flags are set. The packet is then sent to the reader.

NextState: the state of the sensor node is computed by this function which takes the current time stamp as a parameter. *Next-State* is found by multiplying previous state vector probability with the time-stamp square of the transition probability matrix gotten from multiplying the transition matrix time-stamp times, hence the need for a matrix multiplication and copy functions.

SensorNodeHelper class has functions that aid in the installation of sensors onto nodes; *Install* function, setting the attributes that were declared in *GetTypeId* function of the *SensorNode* class with *SetAttribute* which takes the name of the attributes and the value to be set as parameters. There are, of course, the constructors and a function that return a pointer to the associated server.

2.3.3 Device Sims

Rate at which data is generated when device is in use, the quantum of data produced during usage and the number of times the devices are actually used in a day are but a few differences between an event-based, periodic, and real-time sensor devices.

Temperature sensor, Presence sensor, TV remote, Joystick and camera are modelled to depict their change of state with regard to when packets/data are generated by these devices over a day-use period. The devices model of the simulation is based on the usage findings from [2].

- a. *Temperature Sensor*: Only two states which is expected to occur three times in an hour, which translates to seventy two 72 times in a day.
In a simulation time period of a day, *Temperature Sensor* was scheduled to append a packet to the packet vector 72 times. Only one packet is appended on each state change. This is done by calling a *GeneratePacket* function.
- b. *Presence Sensor*: There are three states; *No Presence*, *Short Presence* and *Long Presence*. In a daily use, state changes from *No Presence* to *Short Presence* 10 times and lasts for 10 seconds in the *Short Presence* state and from *No Presence* to *Long Presence* 4 times, for 10 minutes that state.
After replying to a query for identification by the *reader*. It schedules a *GeneratePacketShort* and *GeneratePacketLong* functions to be called 10 and 4 times respectively during the simulation period of a day (86400s). The functions fill up a packet vector during each call for a period of 10s and 10min respectively.
- c. *TV remote*: Multiple buttons could put a *TV remote* in an *In Use* state from a *Not In Use* state. The different button states are two - *Configuration A* and *Configuration B*. There is an equal chance of moving from *Not In Use* state to either *configurations* and when in any of the *Configurations* there is an equal probability of moving to a *Not Pressing* state or staying in the same state but no chance of going to another *Configuration* without first having to go through a *Not Pressing* state. Having same chance of moving to any of other states from the *Not Pressing* state. It is used 10 times a day and lasts for approximately 8s per use.
The *TV remote* class is programmed to fill up the packet vector 10 times in a day of simulation. The generation of the packets lasts for 8s. During this time which the *GeneratePacket* function is called, the various states changes are simulated using Markov. When a *Not Pressing* state is returned, no packet is added to the vector but for the other two states, packets are added to the vector.
- d. *Joystick*: With a three times a day usage and an hour long on each use, the *Joystick* was simulated to have five states - *Not Playing*, *Playing*, *Configuration A*, *Configuration B*, *Not Pressing*. There is equal probability of moving from *Not Playing* state to either *Configuration* states and from *Configuration A* or *B* the *Joystick* moves into a *Not Pressing* state, to a different *Configuration* or stays in it's state, all with equal probability and vice versa

from a *Not Pressing* state.

The generation is packet was scheduled to occur three times and to last for an hour on each call, in a daily simulation, thus changing from *Not Playing* to *Playing* states. In a *Playing* state, a transition is made through all the possible states with equal probabilities. When either *Configuration A* or *Configuration B* is returned, a packet is added to the packet vector and no packet is appended to the vector in the case of *Not Pressing* returned.

- e. *Camera*: Takes a shot of an image size of 25KB which takes approximately 30s to send to the querier.

The *GeneratePacket* function is called as soon as the packet vector is empty, implying the sending of the 25KB data. The packet generation is scheduled at a minute after sending to prevent the camera from seizing the medium.

When a *data request* query is received, the content of the packet vector is checked for emptiness, if empty, the *STATE_NOT_CHANGED* flag is set and reply sent to the header. The *STATE_CHANGED* flag is set, added to each packet in the vector before sending all the packets in the vector, for when the vector is not empty. The memory tag size of each device is set to 256bits (32bytes).

2.3.4 Querier

An RFID reader or interrogator, and in this case, a querier is a bridge between an RFID tag and a controller which, among other things could, read and write data to the tag, power the tag and relay data to and from the controller[8].

Controllers are mainly the part of the system that does the processing of the data on the tags.

Querying of tags is done in a slotted time. In each time slot, a request-for-data packet is sent to the tags with a response of positive or negative data. With TDMA, discussed earlier, slot assignment is static, not responsive to the demand of the volume of data available on tag-augmented sensors hence does not scale in this case. A more scalable and responsive algorithm is proposed in [2], where for each time slot a query is made and based on the outcome of the response to the query, more queries are made to the same tag or not. For a positive response, a reward parameter is increased and the highest reward value in the reward vector

is queried next. Intuitively, a positive response implies query same tag again.

FIGURE 2.4: Class Diagram - Querier

The class diagram illustrating the *Querier* class and its helper class are shown in 2.4.

A discussion of the various function of each class follows next.

StartApplication: the function to run in initializing the application. Socket is created if there are no existing ones bound to the device and connected to a peer address, which, in this case, is a broadcast address. Broadcast is enabled on the socket, a packet-received-callback function is set up and finally the *send* function is scheduled to immediately be invoked.

StopApplication: called during the cancellation of the simulation. Socket is closed and stripped down, the scheduled event is canceled.

Send: the Querier broadcast to all the tags to get an inventory of tags available. This function takes care of that. Packet is created, the broadcast flag in the header is set and sent to the broadcast address.

HandleRead: this is the packet-received-callback function, takes a socket as parameter and invoked when there are packets to be read from the socket file. The header of the packet is checked to determine the type of packet received. If a *broadcast_reply* is received and it is not in the *Querier* inventory, it is added to the inventory. A packet with *data-request* flag is set and sent back to the tag from which the *broadcast_reply* is received.

For a *data_reply* packet type, the reward value of the sending tag is retrieved and the *state_changed* flag is checked to determine if a new data was sent or not. If a new data was sent, the reward vector is updated with a *m_bonus* value and with a *m_malus* value if no new data is received. *SoftMax* is applied to the reward vector, the index with the highest value is gotten which is the same index of the node vector, the *data-request* flag is set and the packet sent to the node with the maximum reward value. This cycle continues till the end of the simulation.

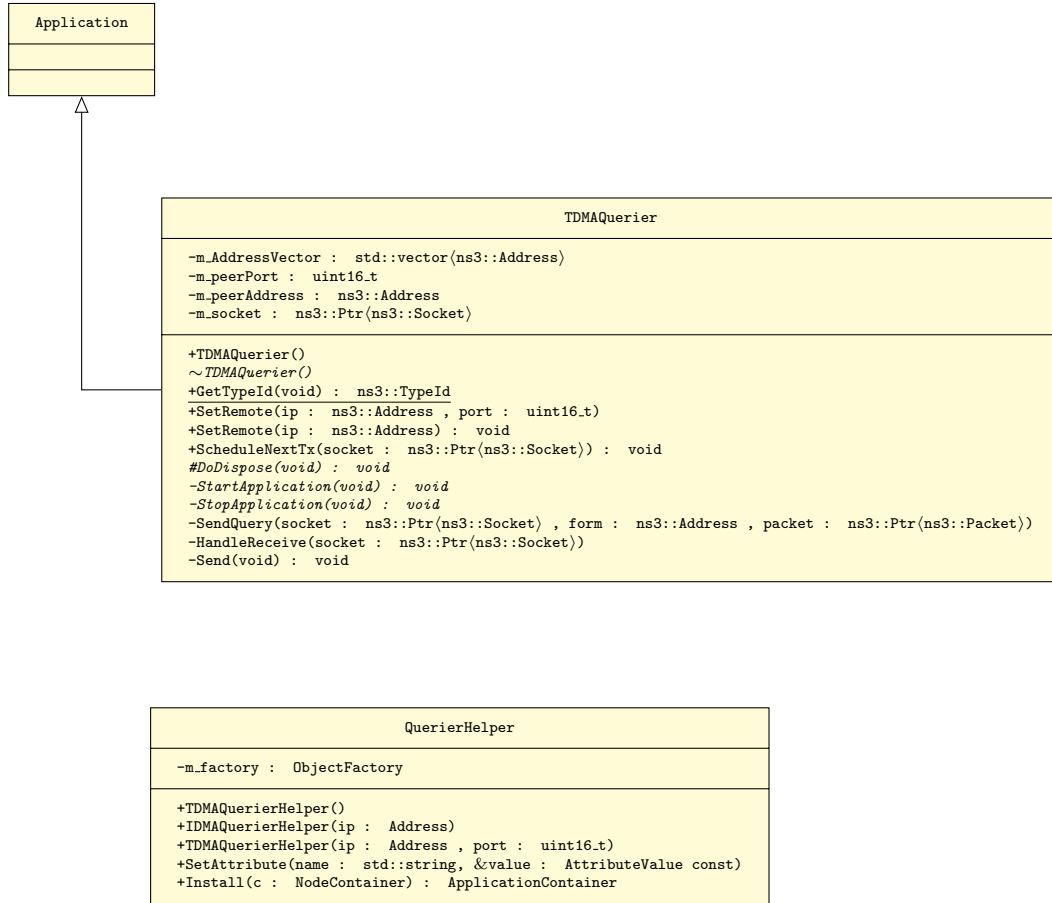

UpdateReward: updates the reward vector. It takes as parameters the reward vector, *bonusORMalus* and the index of node whose reward needs updating. A check is made to determine whether the updating is that of *m_bonus* or *m_malus* and the reward is updated based on 1.2. The function returns the reward vector.

The constructor and destructor functions are included. There two versions of *SetRemote*, one takes only *Address* as parameter and the other *Address* and *port*, they perform the same function of setting up the remote address. *GetTypeId* returns the *TypeId* of the class.

Helper class of *Querier* has similar functions of the *SensorNodeHelper* in 2.3 and they perform virtually the same duties. As a result, a further discussion is omitted here.

2.3.5 TDMA Reader

This reader class is implemented in a TDMA fashion. Each query, which is slotted in a specific time interval, is done sequential and in an endless loop.

The *StartApplication* function is called at the initiation state of the *TDMAQuerier* class. It sets up an IPv4 UDP socket, connects to the broadcast, configures the *SetRecvCallback* function of the *socket* class to *HandleReceive* which reads packet in the socket file, the *Send* function queries for device identification is called next and the finally the *ScheduleNextTx* is scheduled to be called a minute after initiation, at which point all devices should be identified.

The packet type is checked in the *HandleReceive* function, when it is a reply to broadcast identification and the device is not already in *m_AddressVector*, it is added. *ScheduleNextTx* function takes socket pointer as an argument, creates a one-byte packet and schedules *SendQuery* for each device address in the *m_AddressVector* vector to be called at *10milliseconds* apart, it starts again when it gets to the final address in the vector. *10milliseconds* was found to be the least

inter-slot time capable of allowing for the devices to be able to log the parameters of interest. The *SendQuery* function takes socket pointer, address and packet pointer as arguments, it adds *DATA_REQUEST* flag to the header of the packet and sends it off to the designated address.

The *Install* function of the *QuerierHelper* class 'installs' the application on the node. *SetAttribute* sets the various attributes on the *m_factory*.

2.3.6 Example

The simulation is set up here. A number of nodes is created depending on the number of tag-augmented sensors that is of interest. A net-device is installed on each node with a simple wireless channel/media also installed of 640*kbps* data rate. The data rate of the net-device is set at 640*kbps* [9].

Internet stack is added to the nodes and ipv4 is assigned to each network interfaces. One of the nodes is selected and on it is installed the *Querier*, it becomes the reader. The other nodes are the tag-augmented sensors and on each is installed *SensorNode* which is configured depending on whether it be an event based sensor, a real-time sensor or a periodic sensor. The start and stop time of the simulation is indicted and started.

Chapter 3

Results

Discussion of the results takes place in this chapter. The chapter begins with with a description of the data collection process, followed by the parameters considered for performance analysis and ends with discussion of the results obtained.

3.1 Data Collection

With *CreateDatafile* function of each device class, which is called in the *Install* function of the helper classes, log files are created to contain data loss and packet delay values of each device simulated. Packet delay and data loss are the parameters of interest to evaluate the performance of APT-MAC.

Packet Delay: the difference in time between generating a packet data and sending to the reader.

A call to *SetPacketGeneratingTime* function at the end of *GeneratePacket* function sets the time of packet generation and when a packet is sent to the reader, *SetPacketSentTime* is called to set the sending time. The difference is thus the packet delay which is log in the packet delay log file.

Data Loss: this is the produced data that is not delivered to the reader. Calculated by dividing the amount of data sent by the quantum of data produced, the percentage of the result subtracted from 1 is the data loss. Thus it is a percentage.

A counter, *m_newDataCountProduced*, is kept which is increased, a call to

UpdateNewDataProduced(), anytime a new data is produced. The variable, *m_newDataCountSent*, is increased by a call to *UpdateNewDataSent()*, whenever a data packet is sent across to the reader. When *m_queryCounter*, holds the number of times a query is received from the reader by a device and increased with a call to *UpdateQueryCounter()*, gets to 5, *data loss* is computed as indicated earlier and the value log in the data loss log file. The data loss is calculated after every 5 *data-query* request received by the tag-augmented sensor device.

TABLE 3.1: WORKLOAD SCENARIOS DESCRIPTION

No. of Sensors	Scenario	Joystick	Remote	Env. Sensors
20	Case 1	1	2	17
	Case 2	2	3	15
	Case 3	3	3	14
	Case 4	4	4	12
30	Case 1	1	2	27
	Case 2	2	3	25
	Case 3	3	3	24
	Case 4	4	4	22
40	Case 1	1	2	37
	Case 2	2	3	35
	Case 3	3	3	34
	Case 4	4	4	32

The number of packet producing devices (tag-augmented sensor devices) used for the gathering of data and to evaluate the performance of APT-MAC was based on table 3.1. Environment Sensors included the presence and temperature sensors.

3.2 Discussion of Results

Figure 3.1 depicts the transient time, - duration for APT-MAC device to get into optimum performance of reduced data loss and packet delay. The transient time connotes the speed of APT-MAC.

It takes approximately 50ms to get the data loss of a joystick to less than 15%, the designated optimum threshold. That of a presence sensor, on average, it takes

0.283s and with the temperature sensor, it quickly reduces the loss rate at approximately a milli of a second. The data loss of the remote does not get pass the threshold.

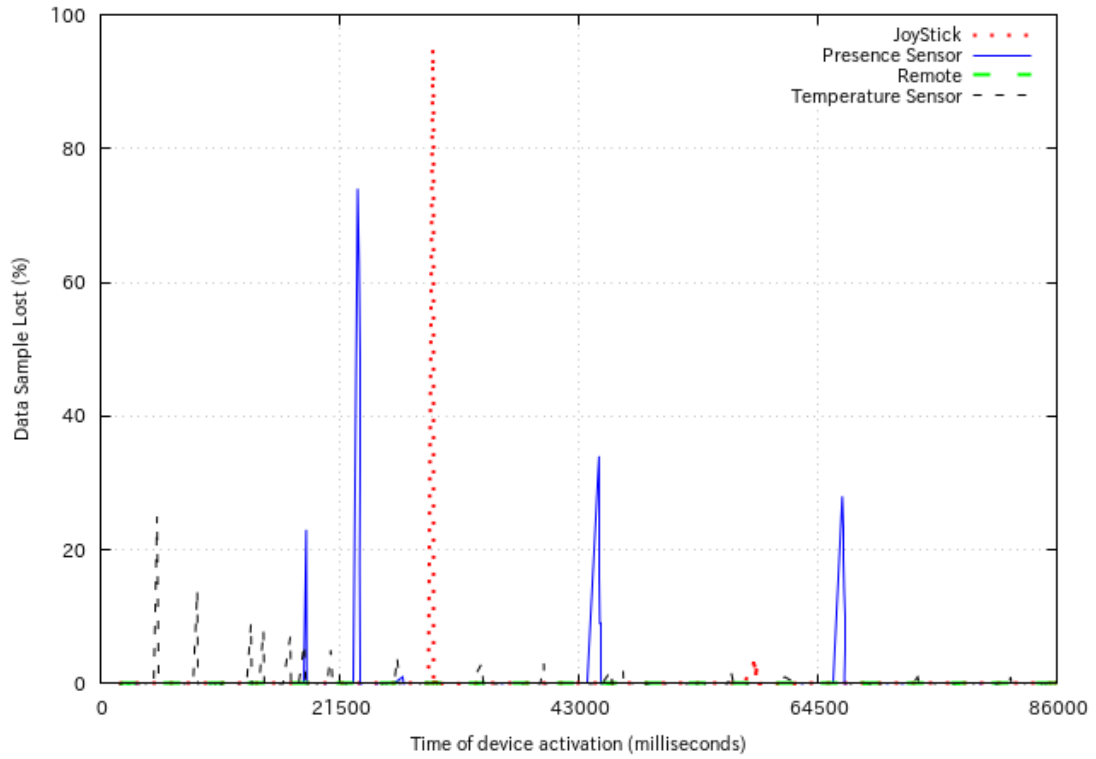

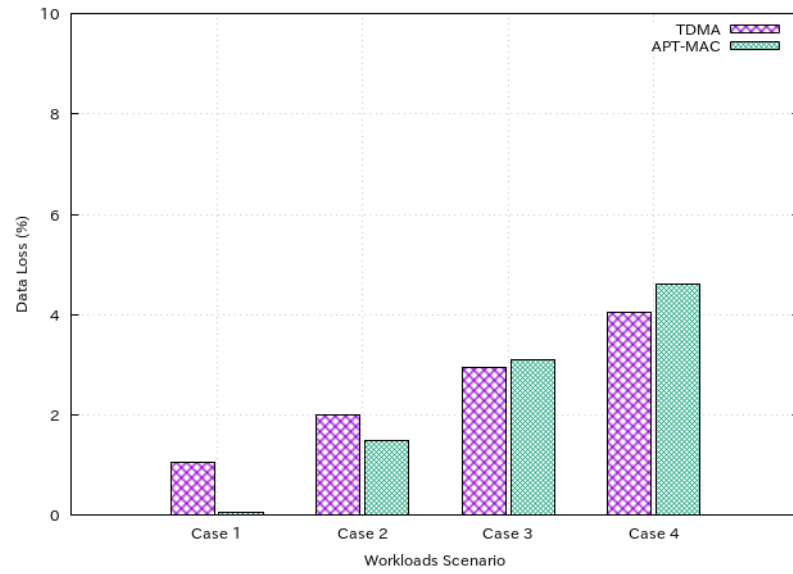

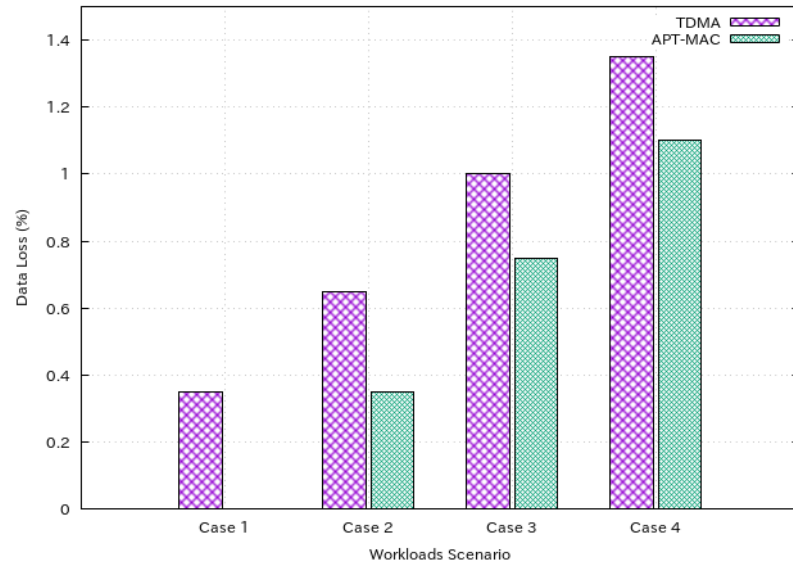

FIGURE 3.1: Transient Time of Devices.

The start times are that of the beginning of data production, which indicates the powering on of the sensory devices.

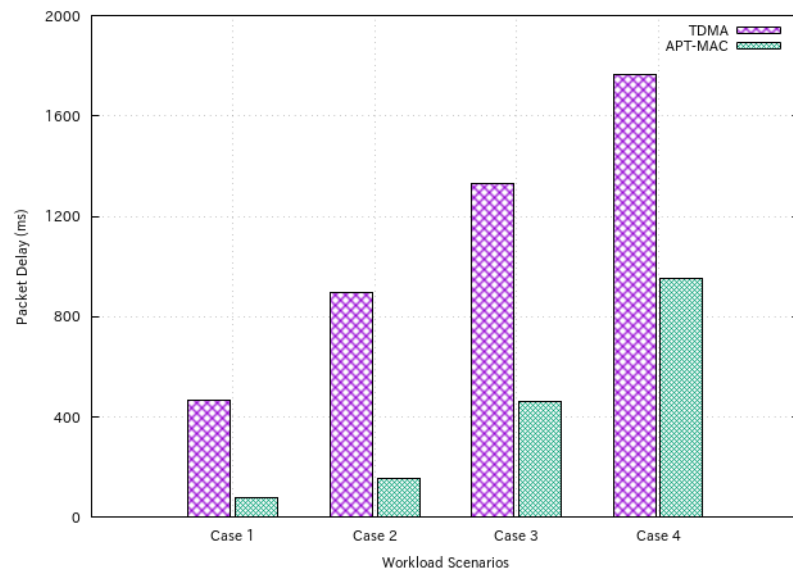

APT-MAC gets better when it is run for a longer time. When the running time for an APT-MAC device is maximized, the better the protocol gets. It can be seen from figures 3.2a and 3.2b, TDMA protocol performs better in the cases 3 and 4 of the short run for 20 devices 3.1.

(A) 20 Devices : Data Loss Short Run.

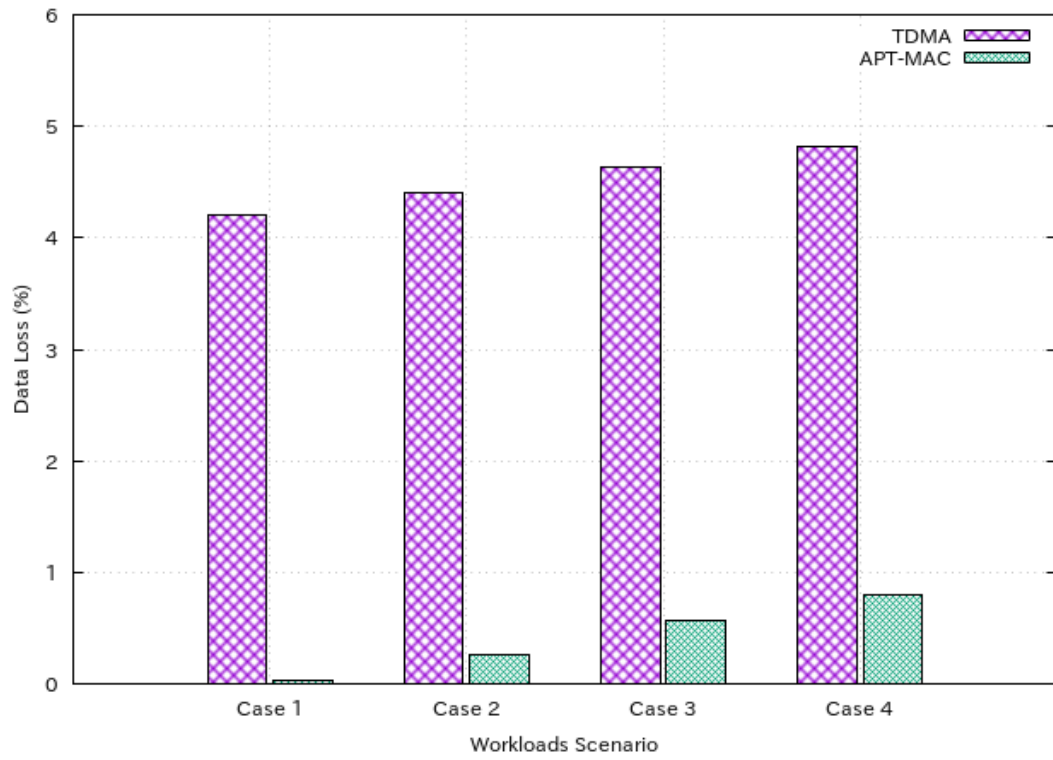

(B) 20 Devices : Data Loss

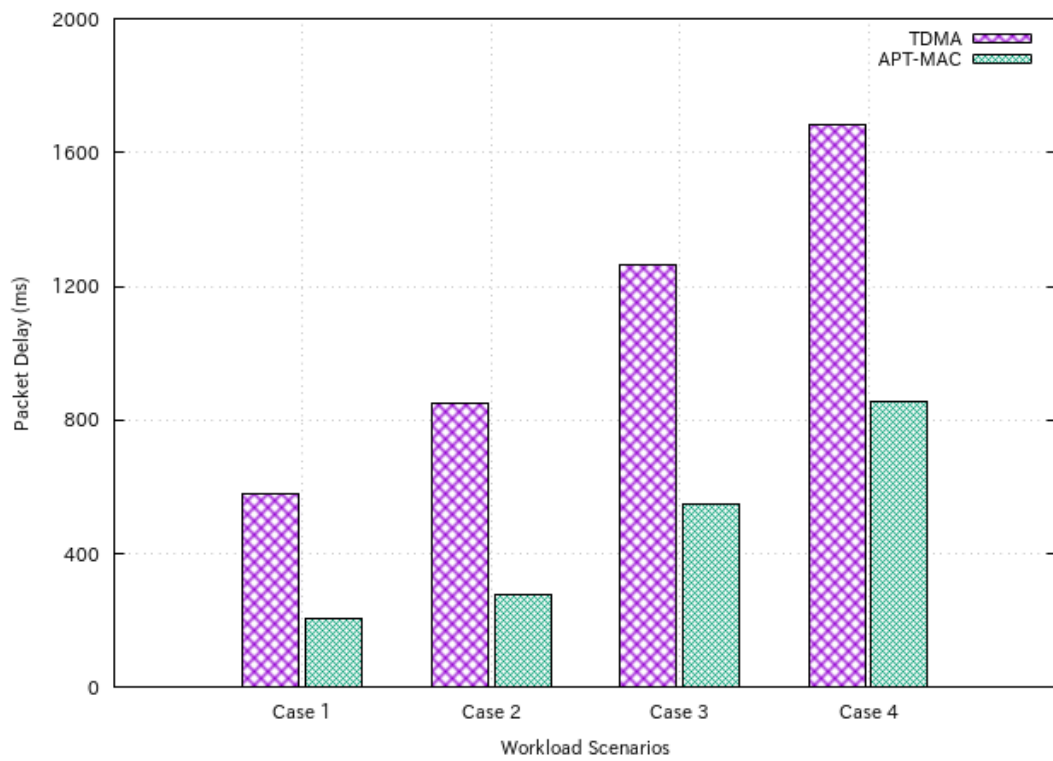

(C) 20 Devices : Packet Delay

FIGURE 3.2: 20 Devices

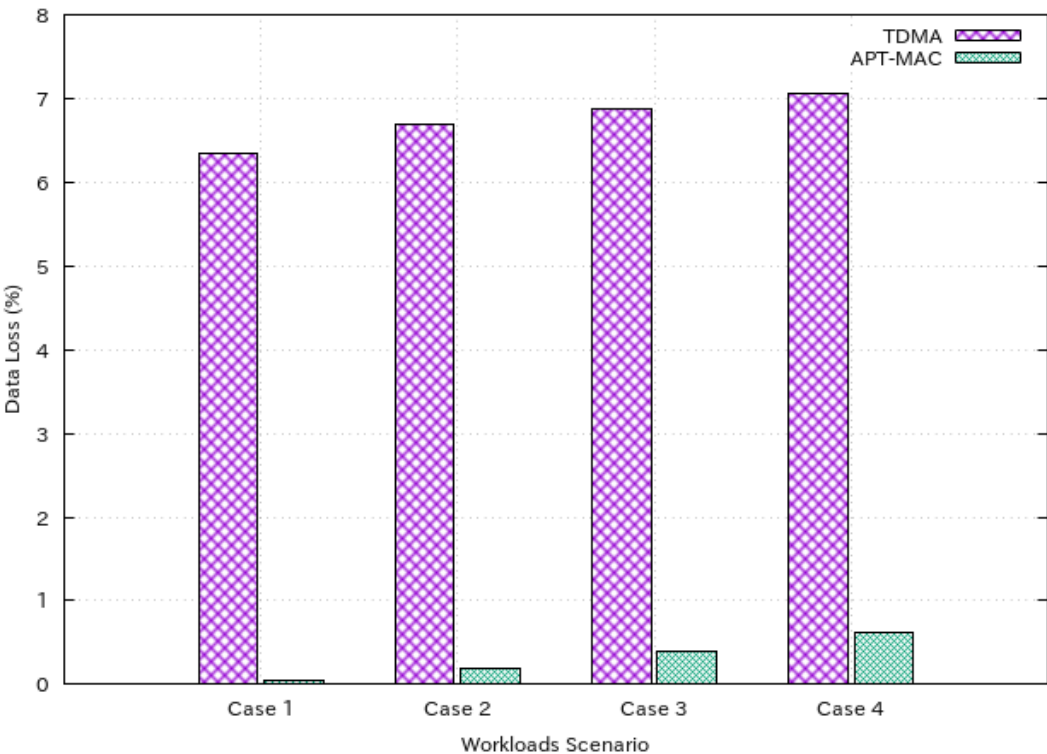

(A) 30 Devices : Data Loss

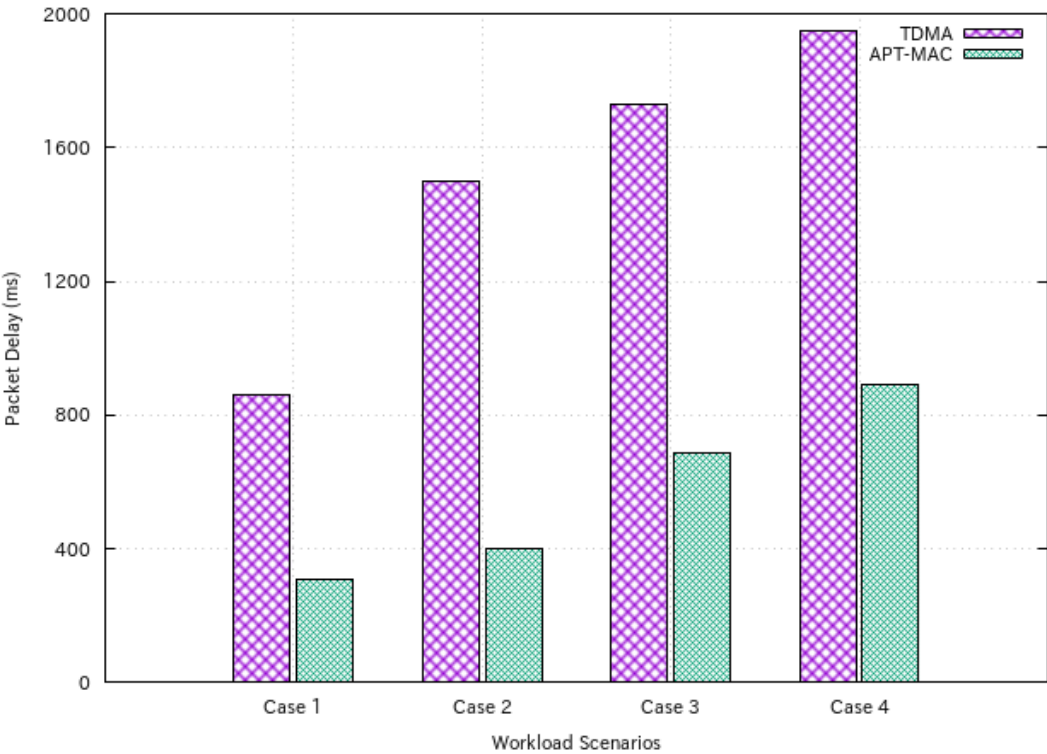

(B) 30 Devices : Packet Delay

FIGURE 3.3: 30 Devices

(A) 40 Devices : Data Loss

(B) 40 Devices : Packet Delay

FIGURE 3.4: 40 Devices

Packet delay, urgency to which packets are delivered to the reader in an equilibrium state, for 20 devices of the various cases in table 3.1 is shown in figure 3.2c. In both APT-MAC and TDMA, the time it takes to deliver new data almost doubles from case 1 to case 2. It doubles for APT-MAC and almost plateaus for TDMA in cases 3 to 4. Generally, APT-MAC delivers new data faster with a worse case (case 4) time of 0.9s while that of TDMA is 1.7628s. On the average, APT-MAC delivers new packet 2.7 faster compared to TDMA - average of 1.115s for TDMA and 0.411s for APT-MAC. Figure 3.3b and 3.4b show packet delay for 30 and 40 devices respectively, similar trend is seen as that of 20 sensory devices with a gradual increases as number of sensory devices increases.

Figure 3.2b depicts the data loss, percentage of new data that is lost as a result of untimely query, for 20 devices. TDMA losses between 0.35% in case 1 to 1.35% in case 4 while APT-MAC does not lose any new data in case 1 and the worse case, case 4, losses 1.10%. The data loss doubles across the various cases for both protocols. The trend is similar as the number devices increases - 30 & 40 devices - figures 3.3b and 3.4b, with the data loss of the APT-MAC being 0.8% and 0.625% for 30 & 40 devices respectively. Proving that the more the sensory devices are the better APT-MAC gets which is contrary to TDMA.

Chapter 4

Conclusion

Simulating a novel medium access control (MAC) protocol, APT-MAC - an adaptive protocol to the data needs of the nodes accessing the medium, on the NS-3 platform was the goal of this experiment. The aim was extended to investigate how the performance of APT-MAC compare to that of TDMA.

The algorithm of the data-requirement-adaptive protocol is based on a solution to the Multi-arm Bandit problem, more precisely ε -greedy algorithm, hence the opening of this documentation sought to shed light on the Multi-arm Bandit problem with its ε -greedy algorithm solution. A brief explanation of TDMA was also introduced. Next, was a description of the actual simulation, the various classes and the task of the various functions used in the simulation. Three categories of tag-augmented data-packet producing sensory nodes were replicated, namely - periodic, event-based and real-time. Both readers, that implementing TDMA and APT-MAC respectively. The focus was turn on measuring the performance of both TDMA and APT-MAC and an elucidation on how the variables of interest - data loss and packet delay - were harnessed.

The results clearly showed that the performance outcome, that is, the percentage of new data that is lost by the sensory devices and the speed, in terms of time, with which a newly generated packet is delivered to reader due to the readers inability or ability to query the tags on time is much better with APT-MAC. In the worse case scenario, data loss and packet delay of APT-MAC were less than 1% and 0.9s respectively, and that of TDMA stood at 7.05% for data loss and almost 2s with TDMA.

4.1 Future Work

A follow up on this investigation could focus on the effects of mobility of the tag-augmented sensory devices on the performance of the protocol. There are other solutions to the Multi-Arm bandit problem, chief among them is the Upper Confidence Bounds [1]. An investigation into which other algorithm could perform better than ε -greedy algorithm is the focus of a future work on this.
